Abstract
Poor dietary intake, prolonged fasting, malnutrition, alcoholism, and protein-based diets may induce ketoacidosis without diabetes mellitus. This is called "starvation ketoacidosis." Here we present the case of a patient diagnosed with starvation ketoacidosis. A 38-year-old female was admitted to our emergency department because of chest and back pain. Electrocardiography and chest X-ray showed no abnormalities. On taking her past medical history, we learned that she had been diagnosed with anorexia nervosa. Anion gap metabolic acidosis with ketone bodies in urine was detected. A diagnosis of starvation ketoacidosis was considered for the patient, and she was treated with dextrose solution for 15 h, and improved acidosis was observed. To the best of our knowledge, there are few case reports on starvation ketoacidosis. Emergency physicians should be aware of the complications of starvation and should immediately start the appropriate treatment.

Keywords: Starvation ketoacidosis, high anion gap, emergency department

Introduction
Ketoacidosis is a metabolic state wherein ketone bodies increase with decreasing serum bicarbonate level and pH. Ketosis may occur during starvation because of poor carbohydrate intake, which leads to lipolysis and ketogenesis (1). Here the brain and other tissues use ketone bodies as an alternative energy source instead of glucose. Although ketoacidosis may be frequently seen as diabetic ketoacidosis in association with type I diabetes mellitus, poor dietary intake, prolonged fasting, malnutrition, gastric banding disorders, alcoholism, therapeutic ketogenic diets (used for the treatment of epileptic seizures, Alzheimer’s disease, Parkinson’s disease, and amyotrophic lateral sclerosis), Atkins diet, and last decade’s famous Dukan diet may induce ketoacidosis without diabetes mellitus (2-8). This is known as starvation ketoacidosis. Here, we present the case of a 38-year-old female with anorexia nervosa who was diagnosed with starvation ketoacidosis.

Case Presentation
A 38-year-old female was admitted to our emergency department because of chest and back pain. Her initial vital signs were normal. Electrocardiography (ECG) and chest X-ray showed no abnormalities. Serum myoglobin, CK-MB, and troponin I levels were within reference ranges. Because of her chest pain and shortness of breath, we ordered her arterial blood gas (ABG) analysis. ABG values were as follows: pH: 7.26, pO₂: 96 mmHg, pCO₂: 24 mmHg, HCO₃: 10.8 mMol/L, and lactate: 1.1 mMol/L. Her urine test showed 4 (+) ketone bodies. On taking a detailed past medical history, we learned that she had been diagnosed with anorexia nervosa. Her family stated that she had not eaten any-
thing for several days. Therefore, we suspected that the patient was in a state of ketoacidosis due to starvation. We consulted the patient to the nephrology department and then started treatment with 50 cc/h of 10% dextrose. We measured blood glucose levels every 2 h and serum electrolytes, ABG, and urine tests every 4 h. After 15 h of treatment initiation, ABG values became normal, and there were no ketone bodies in her urine test (Table 1). Her complaints also ceased. We discharged the patient with the recommendation to follow up with psychiatry and nephrology.

**Discussion**

To the best of our knowledge, few case reports have been published on starvation ketoacidosis. Blood glucose level decreases with decrease in insulin and increase in glucagon during starvation (3). Decreased insulin level leads to increased activity of lipase. Lipase breaks down triglyceride into free fatty acid chains (FFAs). These FFAs oxidize ketone bodies in the liver. A literature search revealed case reports on ketoacidosis due to several reasons, the most common reason being diabetes mellitus. However, our patient had no history of diabetes and nor was she pregnant. She also had no intractable vomiting. She had also no history of alcohol or medicines that may lead to metabolic acidosis. Sepsis may lead to ketoacidosis without diabetes, but her clinical condition did not indicate sepsis (9). Further, she had no history of gastric banding operation. In these conditions, ketoacidosis may be explained by the lack of insulin and poor metabolic function. Ketoacidosis may be life-threatening during lactation. There was a case report on a nondiabetic woman who fasted during lactation (10). There were case reports of ketoacidosis due to low carbohydrate–high protein diets such as Atkins and Dukan (7, 8). We found another case report of severe diabetic ketoacidosis with anorexia nervosa and type I diabetes (11). We investigated the reason for the ketoacidosis in our patient by detailing her past medical history. We finally concluded the diagnosis to be starvation ketoacidosis. The goal of the treatment is to reduce gluconeogenesis. This can be achieved by administering combined dextrose and insulin infusion or dextrose infusion alone (3). Insulin can switch off ketogenesis and provide a more rapid recovery. But during insulin infusion, glucose levels have to be closely observed to avoid hypoglycemia. The recommended treatment time varies from 24 h to 72 h. Occasionally, acidosis state recovers in 24 h following the treatment (3, 8). Our patient recovered after 15 h of her treatment.

**Conclusion**

Starvation ketoacidosis may present as high anion gap metabolic acidosis and may be life-threatening. Because of this reason, emergency physicians should be aware of the complications of starvation and also immediately start the appropriate treatment.
